Male Mosquitoes with Bloodsucking Behavior

Recently, Scientists unearthed the **oldest-known** <u>mosquito</u> **fossils**, dating back 130 million years, has revealed the **bloodsucking behavior in ancient males**. These fossils provide insights into the evolutionary history of mosquitoes and their role as **disease vectors**.

- The fossils represent two male mosquitoes from the Cretaceous Period, possessing elongated piercing-sucking mouthparts typically seen only in females.
 - This discovery suggests that originally all mosquitoes were **hematophagous (blood-eaters)**, regardless of their gender.
 - The male mosquitoes' mouthparts were shorter than those of modern female mosquitoes.
- Mosquitoes are blood-feeders and transmit parasites and diseases to their hosts, including malaria, yellow fever, Zika fever, and dengue.
- The researchers hypothesize that mosquitoes evolved from insects that did not consume blood, with their mouthparts initially adapted for piercing plants to access nutritious fluids.
 - The appearance of flowering plants during the Cretaceous Period may have played a role in the divergence of feeding behaviour between male and female mosquitoes.
- Mosquitoes likely originated millions of years earlier than the discovered fossils, with molecular evidence suggesting their existence during the <u>Jurassic Period.</u>
