

Stellar Nucleosynthesis

Source: TH

Stellar nucleosynthesis is the process by which stars **create the elements inside their cores.** The only element **not formed in this way is <u>hydrogen</u>**, the most abundant and lightest element in the universe.

- Stellar cores have crushing pressures and temperatures, reaching up to 15 million °C in the Sun's core. In these harsh conditions, the nuclei of atoms undergo nuclear fusion.
 - The hydrogen nucleus, which is just one proton, comes together to form helium nuclei (two protons and two neutrons) in the p-p (proton-proton) process.
 - In more massive stars, the carbon-nitrogen-oxygen (CNO) cycle dominates, where the nuclei of these elements come together in different ways to form elements from helium onwards.
 - CNO cycle involves hydrogen fusing into helium, catalysed by carbon, nitrogen, and oxygen isotopes.
 - As a star runs out of nuclei to fuse, its core contracts, increasing the temperature and triggering further nuclear fusion.
 - This process continues until the **star starts producing iron**, the lightest element for which fusion consumes more energy than it releases.
 - Elements heavier than iron can only be synthesised outside a star when it goes supernova.
