

Moiré Materials and Superconductivity

Why in News?

A recent **Nature study** found that **moiré materials** made from <u>semiconductors</u> can also be <u>superconducting</u>, a property **previously** thought to be exclusive to <u>graphene</u>.

What are the Key Facts About Moiré Materials?

- About: Moiré materials are materials having unique properties due to the interference pattern formed when two repetitive structures are overlaid at a slight angle.
- Creation of Moiré Materials: Moiré materials are created by stacking two layers of a twodimensional (2-D) material, such as <u>tungsten</u> diselenide, and twisting one layer at a small angle (3.65^o).
 - The **twist** between the layers creates a **unique moire pattern** that gives rise to **new** electronic behaviors not present in individual layers.
- Electronic Properties: The twist in layers creates flat bands in the electronic structure, where electrons move slowly with nearly constant energy.
 - This slow movement boosts electron-electron interactions, crucial for superconductivity.
- Research on Tungsten Diselenide (tWSe₂): tWSe₂, a semiconductor moiré material, demonstrated superconductivity at a transition temperature of approximately -272.93° C, comparable to that of high-temperature superconductors.
 - The superconducting state in tWSe₂ was found to be **more stable** than in other moiré materials.
- Comparison with Graphene Superconductors: Graphene-based moiré materials achieve superconductivity through electron-lattice interactions and flat band formation, while tWSe2 relies on electron-electron interactions, making it more stable and potentially more robust.
 - Electron-lattice interactions are the interactions between electrons and the atomic lattice (the arrangement of atoms) in a material's crystal structure.
- Significance of Findings: Stable superconductivity at low temperatures enables practical applications in <u>quantum computing</u> and electronics.
 - It can aid in **designing new materials** for future technologies.

Note: Superconductivity is the property of certain materials to conduct direct current (DC) electricity without energy loss when they are cooled below a critical temperature (Tc).

- These materials also **expel magnetic fields** as they transition to the superconducting state.
- Superconductivity was discovered in 1911 by Heike Kamerlingh-Onnes. For this discovery, he won the 1913 Nobel Prize in Physics.
- E..g., MRI machines use an alloy of niobium and titanium.
